Abstract

A study of level of Pb in soils of the centre-north of the Province of Córdoba, a worldwide recognized tourist region for dove hunting, was performed in this work. The native forest of the region has a great population of doves associated with the grains productive fields of the surrounding. Contamination of soils due to hunting activities is regulated by national and local norms. The Córdoba Environmental Secretary by resolution N° 1115/2011 approved a new regulation that categorizes this activity as generator of Y31 (Pb) industrial waste. Lead from pellets alloy is deposited on the soil of the shooting fields. Samples were taken at depth of 50 mm from 315 pits referenced by GPS in accordance with local environmental authorities as well as the hunting outfitters companies. Sampling sites are distributed between parallels 31 °S (S31) up to 30 °S (S30) and between meridians W64 up to W63. Soils samples were analysed by X-ray fluorescence spectroscopy (XRF) while Pb bullets were analysed by scanning electron microscopy (SEM) and X-ray diffraction (XRD). The average concentration obtained for Pb in dry soil sieved (200 mesh) was 80 ppm. Powder XRD patterns of crust material removed from the corroded surface of weathered bullets were obtained. Three Pb mineral compounds were identified by XRD analysis and also studied by optical microscopy and SEM.

INTRODUCTION

Deforestation due to agriculture expansion is threatening the north of Argentina that integrates a part of Semi-arid Chaco region of South America. This is a partial effect of the increase in rainfall that has modified the environment of the subtropical region of Argentina during the last five decades^[1]. The region allows grain cultivation such as soybean, corn, sorghum and wheat. This food source is surrounded by native forest, and the combination of food source and roost has raised the population of *Zenaida Auriculata* (Paloma in Spanish language). This is a consequence that has increased hunting activity in Argentina covered by Argentinean hunting law and resolutions.

Dove hunting cooperates to maintain native forest areas because it competes with deforestation for agricultural purposes. However, a continuous monitoring of lead levels is necessary to set limits to this activity when the values of concentrations are close to the maximum limit allowed. This systematic control should be guaranteed to ensure the sustainable use of natural resources providing equilibrium between regional economy, ecology and sport hunting activities.

Hunters use ammunitions made by a lead antimony alloy where ~ 6% Sb is minority while Pb over 90% is a major component. Metal is not stable during the contact period of bullets in soil. They progressively react and secondary lead minerals phases coated the pellets forming a crust that cover the alloy. During the weathering process grains of crust removed from the coating become an important source of bioavailability of Pb in the biosphere. For this reason it is interesting to describe the mineralogical composition and spatial distribution of Pb species around corroding ammunitions.

In 2011 the environmental authorities of Córdoba regulated the dove hunting activity and consequently our laboratory at Centro de Excelencia en Productos y Procesos (CEPROCOR) received the order to measure the concentration of lead in hunting soils. In this project we used conventional X-ray fluorescence analysis (XRF) to measure Pb in soil samples obtained from 315 sampling pits referenced by GPS, in 36 firing fields of north-east of Córdoba. We also performed the characterization of Pb mineral phases in bullets by X-ray diffraction analysis (XRD) and scanning electron microscopy (SEM). The location of the mineral phases of lead (litharge in the core and dominant hydrocerussite outer crust of bullets) is crucial to understand how the metallic Pb reacts

1
2
3 in the soil solution, as a way to understand the real magnitude of contamination in order
4 to develop efficient remediation programs for those hunting sites [2, 3, 4, 5, 6, 7].
5
6

7 **CHARACTERIZATION OF THE SITE**

8 **Geography of the site**

9
10 The region under study is located in a rectangle area limited by the parallels S30 04.771
11 and S31 21.897 and the meridians W64 17.315 and W63 00.00, as is shown in Fig. 1(a).
12 It was adopted the **World Geodetic System 84** (WGS 84) protocol to show the GPS
13 coordinates in degrees, minutes and thousandths of minutes for latitude (S) as well
14 longitude (W). Samples collection were taken from hunting lands at 150 m of altitude
15 in the east up to 650 m in the west. No samples were taken in the region situated in the
16 surrounding of the “Anzenuza” lake because no sport hunting activities are developed
17 there.
18
19
20
21
22
23
24
25

26 The west side of the study region is crossed by the “North Hill”. This sector
27 corresponds to the Pampeanas Hills that cross the province of Córdoba from north to
28 south. This hill is composed by granitic, metamorphic and sedimentary rocks. The
29 eastern slope of North Hills is smooth (see Fig. 1(b)), with little valleys and small hills
30 ending in the great plain of the east, an important grain area in the centre of Argentina.
31 The highland valleys on the west of the rectangle are dominated by native forest and
32 natural pastures. The low lands of the east called “loess pampa” have a plain relief with
33 a gradient less than 0.3% to the east^[8]. It is crossed by the rivers “Suquia” and “Xanaes”
34 two of the five main rivers of Córdoba. Even these lands are strongly subdivided due to
35 agricultural activities; it is possible to find clusters of native forest of chañar and
36 algarroba trees. These forests are roosting areas for dove life.
37
38
39
40
41
42
43
44
45

46 **Soil**

47
48 East side: The geomorphology of soils from east is “Flat pampa” with plain relief, slow
49 runoff with well drained drainage. The biota consists of grasses and crops. The water
50 table is greater than 8 m presenting climatic, biologic and physics degradation due to
51 anthropic factors as main limitation. The soil can be classified as Argiustol, tipic, from
52 the family of fine limosa^[8].
53
54
55
56
57
58
59
60

1
2
3 North side: The geomorphology of soils is “Mountain sideslopes” with steep relief, slope
4 between 5 – 10%, very rapid runoff, moderate permeability and excessively drained.
5 The soils is classified as Calciustol Petrocálcico^[8]. The biota is composed by
6 heterogeneous forest with autochthonous trees and shrubs. The region has extensive
7 livestock, low infrastructure available and native vegetation.
8
9
10

11 12 13 **Climate**

14
15
16 The study area is extended over a template region. The climate of the region produces
17 two factors for promoting the dove hunting most of the year: diversity of grain crops
18 providing large food supply and pleasant weather conditions for tourist. Argentinean
19 doves do not migrate and they reproduce up to four times a year, providing a year-round
20 hunting.
21

22
23
24 The annual average (1960-present) of rainfall inside the study zone is 850 mm with an
25 annual hydric excess from February to May^[9]. The Normalized Difference Vegetation
26 Index (NDVI) -green index- has a progressive increment since the last three decades.
27
28
29

30 31 **EXPERIMENTAL**

32 33 34 **Soil sample preparation**

35
36
37 In 2012 soils samples were collected in 36 hunting zones placed in the North-East of the
38 Province of Córdoba. They are distributed in an area shown in the rectangle of Fig. 1(a).
39 The sampling procedure consisted to collect soil material on each analyzed site at 50
40 mm depth in 10 GPS referenced points symmetrically distributed in a 100x100m square.
41 Nine sampling points were equally distributed in the square perimeter and one in the
42 centre. Samples collected in the central point were taking at 5 and 15 cm depth. Samples
43 were duplicated, labeled, dated and packed in each hunting zone and were sent to
44 CEPROCOR for analysis and the duplicate samples to local environmental authorities
45 for custodial.
46
47
48
49
50
51
52

53
54 An aliquot of 80 grams of sample was dried in an oven at 60 °C during 24 hs to remove
55 water and volatile compounds. After cooling at room temperature it was carefully
56 grounded using a porcelain mortar to reduce the granulometry to dust. This material was
57
58
59
60

1
2
3 sieved in a plastic sieve of 200 mesh (74 μ m). Finally, 4 g of this powder were mixed
4 with 1 g of cellulose and pressed at 20 tons in a matrix of 40 mm diameter. The pressed
5 pellet samples obtained after different experimental tests were very stable, without
6 surface or border failures. To assure the traceability, a numerical code was applied to
7 each pressed pellet sample and correlated with the original raw material storage package
8 and also with the powder recipient before blending. A database computer program
9 saved each code with information about geomorphology setting, the analytical
10 procedure and the post-analysis location of the XRF disk, powder and original raw
11 material for control.
12
13
14
15
16
17

18 XRF

19
20
21
22
23 Multielemental quantitative analysis of elements from Na to U was performed by XRF
24 spectrometry in 315 soil samples from 36 hunting sites located on east and north sides
25 of the rectangle of Fig. 1(a).
26

27
28 The Resolution 1115/11 of the environmental authorities of the Province of Córdoba
29 established that Pb concentration must be determined in dried and sieved soil (mesh
30 200, 74 μ m). This procedure excludes to grind the bullets that remain retained on the
31 sieve. The XRF quantification carried out by our laboratory at CEPROCOR reported the
32 amount of lead in sieved soil after removing the weathered pellets.
33
34
35

36
37 Fluorescence intensities were measured using a 4 kW power Bruker SRS 3400
38 wavelength dispersive spectrometer. The x-ray tube has a thin Be window (75 μ m) to
39 optimize the detection limit. The spectrometer includes six Bragg analyser crystals,
40 OVOB, OVOC, OVO55, PET, LIF 200 and LIF 220, allowing it to measure elements
41 from Na up to U. Pb La_1 x-ray fluorescence intensity was measured using a LIF 200
42 crystal, fine collimator of 0,15°, voltage 60 kV, electric current intensity of 67 mA,
43 mask 34 mm and vacuum mode. Both detectors flow counter and scintillation counter
44 were used simultaneously^[10].
45
46
47

49

50 pH determination in soil

51
52
53
54 The properties of soil like organic matter and pH develop an important function in the
55 weathering of metallic Pb bullets in dove shooting fields. The soluble secondary
56 minerals obtained from transformation of Pb bullets are a mechanism for Pb
57
58
59
60

1
2
3 mobilization in soils. In presence of organic matter and low pH the transformation of
4 metallic Pb to secondary Pb-minerals are more rapid. Lower soil pH is determinant to
5 increase the solubility of Pb providing more mobilization of Pb into the soil. On the
6 other hand, reducing organic matter and increasing soil pH slowed weathering of
7 metallic Pb in a soil^[11]. No organic matter in soil was determined in this work.

8
9
10 Soil pH was determined following the procedure of USEPA Method 9045D (2004)
11 Soil and Waste pH at a soil to deionized water ratio of 1:2 (w/v), using pHmeter with
12 glass electrode Sartorius model PP-20. Soil pH was determined for samples
13 corresponding to the central point (5 mm depth) of each analyzed site of 100m x 100m
14 square.
15
16
17
18
19

20 21 Crust samples

22
23
24 Ammunition retained in soil samples sieving were separated and classified. Most of
25 them look coated by a crust of brown and gray material as a cause of weathering
26 conditions. A powder product of this corrosion crust was obtained by mixing groups of
27 15 bullets during 15 s. The method was developed by our laboratory and the optimized
28 time was determined controlling the quantity and crystallinity of the crust power
29 removed from the bullets. Too much time may produce altered crystals while fewer
30 seconds may not disperse clusters of crystals.

31
32 Powder X-ray diffraction patterns were collected with a Bruker AXS D8 Advance
33 diffractometer operated with a Cu K α x-rays source and a post-diffraction graphite
34 monochromator, at 40 kV, 40 mA. The powder was loaded over zero background
35 silicon sample holder. During the data collection, the sample holder was rotated in a
36 plane parallel to its surface at a speed of 30 rpm to reduce preferred orientation effects.
37
38 The powder mounts were scanned over a Bragg angle from 2° to 70° 2 θ , with a step
39 size of 0.05° 2 θ and count time of 9 seconds per step.

49 RESULTS

50 51 Soil Analysis

52
53
54
55 XRF quantification was carried out by a standard addition curve of Pb in a mixture of
56 uncontaminated soil, in a concentration range from 0 to 1000 ppm. The lower detection
57
58
59
60

1
2
3 limit for Pb in soil was determined in 15 ppm assuming a limit of quantification of 40
4 ppm for this work. This value was empirically determined and supported by reasonable
5 experimental data. The background level of lead in soil of 40 ppm was calculated by
6 extrapolating the standard addition curve to none fluorescent intensity. Other authors
7 have determined lead concentrations lower than 50 ppm in uncontaminated soil, but in
8 many urban areas those exceed 200 ppm^[11, 12, 13].

9
10
11
12
13
14 Figure 2 shows the x-ray fluorescence spectrum of a sample of soil taken from a hunting
15 activity pit belongs to region E delimited by the rectangle of Fig 1(a). The linear X-scale
16 selected for XRF spectrum allows to superimpose scans measured with different
17 crystals, showing the spectrum easily readable, well spread on the whole useable range
18 for XRF (from about 30 keV to 0.13 keV in our equipment). That is the reason why the
19 X-scale is labeled $7.5 - \sqrt{E}$, where 7.5 has been arbitrarily chosen in order to reach the
20 energy limit for C K α lines.
21
22
23
24

25
26 Table 1 shows the concentration of the major elements in soil corresponding to the
27 spectrum of Figure 2.
28

29
30
31 Lead concentration results for 315 soil samples collected from 36 sport firing sites are
32 shown in figure 3. The histogram represents the distribution of Pb concentrations for all
33 dove hunting sites located on the region delimited by the rectangle studied. The
34 concentration range goes from 40 (lowest quantification limit) to 474 ppm as maximum
35 value obtained. The average concentration value for Pb was calculated in 80 ppm.
36
37

38
39 Figure 4 shows the correlation between the values of soil pH and total Pb concentration
40 values obtained for soil samples of the 36 firing sites measured. It can be seen that
41 higher values of Pb were found in acid soils.
42
43
44

45 Analysis of crust

46
47
48 Powder XRD qualitative analysis of the phases was performed by the DIFFRACplus
49 EVA® software (Bruker-AXS, Germany) based on the ICDD Powder Diffraction File
50 database (PDF card numbers 33-1161, 24-0586, 13-0131, 05-0561 and 04-0686).
51

52
53
54 Figure 5 shows the PXRD patterns of mineral phases of crust removed from bullets of
55 zones H and F (north) and zone E (east) of the region represented by the rectangle in
56 Fig. 1(a). Encrustation of Hydrocerussite ($\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2$), Litharge (PbO-tetragonal)
57
58
59
60

1
2
3 and Hydroxypyromorphite ($\text{Pb}_5(\text{PO}_4)_3(\text{OH})$) were found in this work. Quartz appears as
4 an adhering soil contamination in crust, it is not a mineral phase formed from pellets
5 composition. A small amount of metallic lead was identified in samples of both zones.
6
7

8 9 10 Optical, laser and Scanning Electron Microscopy (SEM)

11
12 A Motic optical microscope (40x) was used to observe the whole spheroids bullets and
13 a Lext 3D Laser microscope OLS 4000 Olympus to observe the crust grown in the
14 surface of the pellets. All these apparatus belong to LAMARX at the Facultad de
15 Matemática, Astronomía y Física (FAMAF) of the University of Córdoba. Figure 6(a)
16 shows a microphotography of a weathered bullet collected in soils of a firing field of the
17 zone F (north) of the region studied. It is possible to observe the altered surface of the
18 Pb alloy of the original ammunition. White zones correspond to hydrocerusite on a grey
19 background of litharge, quartz and Pb. In Figure 6(b) it is shown a microphotography
20 1400x of a region of the bullet surface of Fig 6(a) showing hydrocerusite crust (white
21 zones).
22
23

24
25 Figure 7(a) shows a microphotography of an isolated crust grain removed from the
26 surface of a bullet. Figures 7(b), 7(c) and 7(d) show three SEM spectra taking from
27 different zones on the grain where the presence of chemical elements of mineral
28 compounds were identified. The original alloy of bullets contains a small percentage of
29 antimony being this the reason to be present in Fig 7(b) for instance. But, Sb mineral
30 compounds cannot be detected by XRD because these phases present limited
31 crystallinity, being almost amorphous. It is also possible to identify the element
32 phosphorus in the spectrum of Fig. 7(d) possible due to the presence of
33 hydroxypyromorphite. Finally, calcium is attributed to soil contamination.

45 46 **CONCLUSIONS**

47
48
49 The first study concerning the quantification of lead in dried sieved soils from fields
50 dedicated to dove hunting was carried out in this work. XRF spectrometry was used to
51 quantify 315 samples of soil collected in 36 firing sites of Argentina and processed in
52 CEPROCOR. An innovative written protocol approved by the Córdoba State
53 environmental authorities was used for sampling and quantification.
54
55
56
57
58
59
60

1
2
3 Results show that the average concentration value of Pb for sieved and dried soils is 80
4 ppm. Only four samples showed values of concentration of Pb above the guidance level
5 of 375 ppm for farmland established by the Argentinean Law N° 24,051. All these cases
6 correspond to measured fields located far from the agricultural border.
7

8
9 The average lead concentration is two times the value determined for natural soil of
10 lands without human activity. Lead quantification performed in this work do not
11 included the bullets found in the raw material used to process each sample because these
12 pellets were removed by sieving the soil. No statistical calculation was made to
13 determine the average number of pellets found in the material of samples, nor the total
14 amount of pellets deposited each year in the study area. But, it could be hypothesized
15 that pellets will continue their weathering process releasing Pb to soil in the future.
16 There is an amount of Pb sources in each hunting site which has not yet completely
17 'weathered'. As these pellets continue reacting with the components of soil, the
18 concentration of 'potentially mobile' Pb phases will increase in soil.
19

20 This fact requires to local authorities to continue monitoring periodically the
21 concentration of Pb in soils of hunting sites to guarantee the sustainability of natural
22 resources. When levels of lead concentration reach higher values than those permitted
23 by the applicable environmental standards phytoremediation is inevitable for use of this
24 land for pastoral or farming
25

26 This study also determined the species of encrusted mineral phases in the pellet surface
27 due to reaction of metal in soil. XRD results showed that the transformation products in
28 the crust material are predominantly Hydrocerussite associated with minor amounts of
29 litharge and not well crystallized Hydroxyromorphite. Special attention was paid to the
30 identified phase Hydroxyromorphite ($\text{Pb}_5(\text{PO}_4)_3(\text{OH})$) because the presence of P.
31 We are now studying if this compound is due to waste of fertilizer released in soils of
32 grain lands in the borders of forest or just due to presence of natural apatite in soil.
33

34 Our laboratory is developing a project in progress for micro synchrotron radiation XRF
35 and micro XANES mapping in crust to improve the identification, distribution and
36 quantification of mineral phases of Pb as well Sb in weathered pellets as a continuity of
37 these results.

Table 1

Compound Formula	Concentration %	X-ray Characteristic line Measured
Na ₂ O	1.39	Na Kα ₁
MgO	1.18	Mg Kα ₁
Al ₂ O ₃	16.3	Al Kα ₁
SiO ₂	66.2	Si Kα ₁
P ₂ O ₅	0.43	P Kα ₁
SO ₃	0.18	S Kα ₁
Cl	0.036	Cl Kα ₁
K ₂ O	1.86	K Kα ₁
CaO	2.27	Ca Kα ₁
TiO ₂	0.92	Ti Kα ₁
MnO	0.108	Mn Kα ₁
Fe ₂ O ₃	6.46	Fe Kα ₁
CuO	0.012	Cu Kα ₁
ZnO	0.017	Zn Kα ₁
Rb ₂ O	0.021	Rb Kα ₁
SrO	0.055	Sr Kα ₁
Y ₂ O ₃	0.005	Y Kα ₁
ZrO ₂	0.036	Zr Kα ₁
PbO	0.023	Pb Lβ ₁

FIGURES CAPTION

Figure 1: a) Geomorphologic map of the Province of Córdoba and the study region of this work (black line rectangle). b) The line O-E represents the latitude S30 20.000 where the geomorphologic profile shows the terrain relief characteristics.

Figure 2: X-ray fluorescence spectrum of a sample of soil collected from a hunting activity pit of the zone E of the study site bounded by the rectangle in Fig. 1(a).

Figure 3: Histogram of lead concentration determined by XRF analysis for all soil samples measured.

Figure 4: pH of soil samples correlated to soil total Pb concentration.

Figure 5: XRD patterns for mineral phases of crust obtained from a pool of bullets of north and east samples.

Figure 6: a) A photograph (Motic 40x) of a weathered bullet. b) Microphotography 1400x taken by a Lext 3D Laser microscope OLS 4000 Olympus of crust.

Figure 7: a) Microphotography of a grain crust remove from a bullet surface. b) SEM spectrum of point 3. c) SEM spectrum of point 4. d) SEM spectrum of point 5 showing the presence of P.

TABLES CAPTION

Table 1: XRF spectrometry of soil showing the composition of a sample collected from a hunting activity pit in the east of the study site bounded by the rectangle of figure 1.
